Level of cardiovascular fitness and its relationship with physical activity and body mass index in young adults of Islamabad

Zainab Khatoon1, Muhammad Afzaal Afridi2, Taqdees-e-Maryam3, Afifa Gull4, Hania Farheen5

Abstract

Objective: To determine the level of cardiovascular fitness in young adults, and to find the relationship of maximum oxygen uptake with body mass index and physical activity.

Methods: The cross-sectional study was conducted at two private universities in Islamabad, Pakistan, from January to June 2019, and comprised subjects of both genders aged 18-25 years with normal cardiopulmonary system. Physical activity was measured using the short form of International Physical Activity Questionnaire, while maximum oxygen uptake was measured using the Bruce protocol. Data was analysed using SPSS 24.

Results: Of the 321 subjects, 59(18.4%) were males and 262(81.6%) were females. The overall mean age was 21.15±1.73 years. Overall, 152 (47.3%) subjects had normal body mass index, 86(26.8%) had high level of physical activity, and 85(26.5%) had moderate level. With respect to to maximum oxygen uptake, 28(47.5%) of the males were in the superior category, while 72(27.5%) women were in the good category. All the vitals along with dyspnoea and fatigue showed significant difference (p≤0.05) except oxygen saturation (p=0.062). Maximum oxygen uptake showed negative weak (p=0.40) correlation with body mass index and weak, positive and significant correlation (p=0.007) with physical activity.

Conclusion: Majority of the young adults were found to be active as indicated by the levels of their maximum oxygen uptake and physical activity. Significant correlation was found between cardiovascular fitness and physical activity.

Introduction

In today’s world, cardiovascular fitness has become a rising concern with the sudden but significant fall in physical activity. Heart diseases have been found to be the leading cause of mortality, according to Centres for Disease Control and Prevention (CDC) and the World Health Organization, accounting for 17 million deaths worldwide annually.2,3 Low cardiovascular fitness accounts for an estimated 12% of all deaths in the United States.1 Lifestyle modification and risk factor reduction can reduce this increasing death rate due to cardiovascular diseases.1

The WHO has also reported that around 3.2 billion deaths each year are attributed to lack of physical activity.4 The level of maximal oxygen uptake (VO2max) serves as a suitable measurement of the level of physical exercise and cardiovascular endurance in an individual. VO2max is defined as the maximum level of oxygen delivered and utilised during intense exercise.3

Cardiovascular fitness is a unit of measure of a person’s physical fitness. Since physical fitness is the ultimate metric in the measurement of most, if not all, of body’s functional systems,5 therefore cardiorespiratory fitness can be passed on as a measure of body’s functional system’s condition.1

Childhood and adolescence, which serve as a crucial base towards the development of a young adult as in these phases not only significant psychological and physiological developments take place, but baseline determinants of lifestyle and behaviour are also established. It has also been reported that approximately 32% Americans are obese, and a vast majority of US adults do not engage in regular physical activity.6 This is due to the fact that lack of physical activity induces obesity, and obesity further discourages activity. This never-ending relationship between obesity and physical activity may lead to worsened cardiorespiratory endurance.

Adults who were overweight when they were children have higher levels of lipoproteins, blood pressure and fasting insulin levels and, thus, are at increased risk for cardiovascular disease compared to adults who were slim as children.7

Several studies have listed top five risk factors leading to death as high blood pressure (BP), smoking, high blood glucose and obesity, and all these are connected with physical inactivity.1,4 Alongside the increase in these risk factors, there is decline in many physiological systems owing to ageing, in addition to loss of muscle mass, decline
in balance ability, reduction in muscle strength and endurance and decline in cognitive performance. All these have a significant impact on one’s functional independence.

The current study was planned to determine the level of cardiovascular fitness and physical activity in young adults, and to find the relationship of VO2max with body mass index (BMI) and physical activity.

Subjects and Methods

The cross-sectional study was conducted from January to June 2019 at two private universities in Islamabad, Pakistan. After approval from the ethics review board of Shifa International Hospital, Islamabad, the sample size was calculated using Rao software while assuming the young adult population to be 864,099 with a confidence interval (CI) of 95% and 5% margin of error. The sample was raised using non-probability convenience sampling technique. Those included were young healthy adults aged 18-25 years. Those excluded were individuals with anaemia, pulmonary and cardiovascular diseases, history of thoracic surgery, active/passive/retired smokers and those with any active pathology. All the parameters were excluded by detailed history, general physical assessment and cardiopulmonary system assessment.

Data was collected after taking written informed consent from each subject.

The data-collection tool was a self-designed questionnaire, covering demographic data, past medical history, BMI, assessment of cardiovascular fitness with maximal heart rate (MHR), target heart rate (THR), Bruce protocol outcomes, like VO2max, total run time (TRT), total metabolic equivalent of tasks (METS), VO2max categories and pre- and post-monitoring chart of the vitals, including HR, oxygen saturation, fatigue, Borg scale and BP readings, accompanied by the short form of the International Physical Activity Questionnaire (IPAQ-SF).

Weight and height were measured by weight machine and stadiometer respectively BMI was calculated using standard formula of weight (kg)/ height (m²). Participants were classified as Underweight(<18.5kg/m²), normal (18.5-22.9 kg/m²), overweight (≥23kg/m²), at risk (23-24.9 kg/m²), obese class 1 ( 25-29.9 kg/m²) and obese class 2 (≥30kg/m²) categories using standard WHO criteria for Asia Pacific Region. Vitals, including oxygen saturation and rather, were measured by digital pulse oximeter (Believia Electronics). BP was measured using standard mercury sphygmomanometer. Respiratory rate was calculated manually by a physical therapist, whereas dyspnoea and fatigue were measured using the modified Borg scale and the fatigue rating scale.

Bruce protocol was used to measure VO2max. Pre-test vitals were noted. The subjects were given guidance over how they can stop the test process in case they felt over-exhausted or started to get symptoms of calf pain and shortness of breath. Other reasons of termination were participant’s denial and THR achieved. At the completion of Bruce protocol, participant’s post-test vitals were noted. The outcome measures in all the participants were assessed by a professional physical therapist to ensure uniformity. In the end, total runtime and gender was used to calculate VO2max using the formulas, VO2 max = 14.8 – (1.379 * T) + (0.451 * T2) – (0.012 * T3) for men, and VO2max = 4.38 * T – 3.9 for women.

The participants were classified into superior, excellent, good, fair, poor, and very poor categories of VO2max.

Data was analysed using SPSS 24. Mean and standard deviation was calculated for quantitative variables, like age, MHR, THR, total time on treadmill, VO2max and IPAQ score. Frequencies and percentages were calculated for qualitative variables, like gender, BMI, reason for termination, level of physical activity, VO2max categories according to age and norms for males and females. Shapiro Wilks normality test was applied on all baseline variables and p<0.05 for all the variable indicated that the data was not normally distributed. The test of choice was Wilcoxon signed rank test for inter-group comparisons. Spearman correlation was used to assess the relationship of VO2max with physical activity and BMI.

Results

Of the 351 subjects approached, 321(91.5%) participated. Of them, 59 (18.4%) were males and 262 (81.6%) were females. The overall mean age was 21.15±1.73 years. Overall 152 (47.3%) subjects had normal BMI, 56 (17.4%) were underweight, 32 (9.96%) were at risk, 16 (4.98%) in obese class 1 and 65 (20.2%) were found to be in obese class 2 category. The reason of termination of the Bruce protocol was calf pain for 120 (37.4%) subjects, followed by shortness of breath 107 (33.4%), exhaustion 87 (27.1%), participant’s denial 4 (1.2%) and THR achieved 3 (0.9%). Mean MHR, THR, total time on treadmill, VO2max and IPAQ score were noted (Table 1).

SD: Standard deviation, B/M: Beats per minute, IPAQ: International physical activity questionnaire.

Table-1: General characteristics.
Lowest category of IPAQ score was found in 150(46.7%) subjects, followed by highest 86(26.8%) and moderate 85(26.5%) categories. Age wise categories of VO$_2$max for men aged 13-19 years and 20-29 years were 9(15.3%), and 50(84.7%), while the corresponding values for women were 57(21.8%) and 205(78.2%). According to VO$_2$max norms, 28(47.5%) men were in the superior category, while 72(27.5%) women were in the good category (Figure).

In terms of vitals, systolic blood pressure (SBP) and diastolic BP (DBP), respiratory rate and HR showed significant difference between pre- and post-Bruce protocol readings ($p<0.05$) except oxygen saturation ($p=0.062$). Other variables, including dyspnoea and fatigue, also showed significant difference ($p<0.05$) (Table 2). VO$_2$max and physical activity showed a weak positive but significant correlation ($r=0.15$, $p=0.007$), while VO$_2$max and BMI showed a weak negative and non-significant correlation ($r=-0.046$, $p=0.409$).

In terms of vitals, systolic blood pressure (SBP) and diastolic BP (DBP), respiratory rate and HR showed significant difference between pre- and post-Bruce protocol readings ($p<0.05$) except oxygen saturation ($p=0.062$). Other variables, including dyspnoea and fatigue, also showed significant difference ($p<0.05$) (Table 2). VO$_2$max and physical activity showed a weak positive but significant correlation ($r=0.15$, $p=0.007$), while VO$_2$max and BMI showed a weak negative and non-significant correlation ($r=-0.046$, $p=0.409$).

**Discussion**

The study determined the level of cardiovascular fitness in young adults, and found that 47% subjects had low physical activity levels, while 53% were sufficiently active in moderate and high categories of physical activity. Similar results were reported in another study.15 Contrary to the current results, a study reported that majority of young adults had low physical activity levels, with only 17% falling in moderate to vigorous physical activity levels.16 This difference in physical activity levels might be due to the different culture, target population and testing protocol. Changes in testing protocols and characteristics of target population can affect the results. The current findings showed that mean value of VO$_2$max was in the good category. However, categorical distribution of VO$_2$max showed that males had better values than females. Similar findings were reported earlier,11 while contrasting findings have also been reported.17

Greater VO$_2$max in males might be due to the reason that they are taller, having greater muscle mass and lower BMI. In present study, the findings of pre-test and post-test HR, SBP and DBP showed high significance. Similar results were reported by two studies.18,19

SBP was found increased because afferent signals are sent from the exercising muscles to the brain, stimulating the sympathetic centre and causing a rise in HR and cardiac output and resulting in SBP increase.20

However, conflicting results were found in the studies mentioned above for DBP.14,15 This conflict might be due to the differences in testing protocols.

The findings of oxygen saturation in the current study showed a very small change, where means for pre-test and post-test showed a 0.2% increase. On the contrary, studies showed a mean change in oxygen saturation before and after test as 0.5% and 0.86%, but as a decrease, as opposed to increase in the current study.18,19 This contradiction may be attributed to human error, such as delay in the measurement of oxygen saturation can show an increase in the readings.

The present study showed weak positive and significant correlation between VO$_2$max and physical activity levels, showing that increase in physical activity increases VO$_2$max. The correlation between physical activity and VO$_2$max was also observed in different studies.17 One of the possible explanations for this correlation might be that during any physical activity or exercise, adaptations occur in human body to increase the metabolic rate, resulting in most of the adaptations in cardiopulmonary system.21 Researchers have proven that one of the most important factors affected during physical activity is VO$_2$max that is the predictor of aerobic power, so the conclusion is that regular physical activity may enhance aerobic power.21

Furthermore, weak negative and non-significant correlation was found between VO$_2$max and BMI in the current study. Similar correlation was found earlier.22

Contrary to the results, negative but significant relationship was found in a study.23 This difference in results might be
due to the different protocols used in the studies. Further, correlation of VO\textsubscript{2max} and BMI was seen at different categories of BMI and at different stages of exercise.\textsuperscript{20} VO\textsubscript{2max}, which indicates total body oxygen consumption, depends on ventilation and cardiac output. In obesity, due to accumulation of fats, lungs’ capacity to increase the ventilation is impaired which affects VO\textsubscript{2max}. Obesity also limits cardiovascular endurance with increase in workload. So increase in obesity can lead to decrease in cardiovascular fitness, which might be one of the possible reasons for the negative relationship of BMI with VO\textsubscript{2max}. Therefore, daily physical activity in early age of life should be promoted for better performance, and to increase muscle endurance.\textsuperscript{23}

The current study has a few limitations, like male-female ratio being not equal in the sample. Also, VO\textsubscript{2max} and IPAQ were not assessed by gold standard tools, like VO\textsubscript{2max} machine and accelerometer respectively.

**Conclusion**

The majority of the young adults were found to be active, as indicated by their VO\textsubscript{2max} values and physical activity levels. Cardiovascular fitness was found to be related to physical activity, and physical activity was an important stimulus of aerobic capacity improvement. However, the correlation between cardiovascular fitness and BMI was not of any statistical significance.

**Disclaimer:** The institutional review board (IRB) was the same for two studies, conducted by two different groups of medical students. The current study is Phase 1, while phase 2 of the project relates to “effect of -intensity interval training versus continuous moderate training on peak VO\textsubscript{2max} in young adults of Islamabad”. The inclusion criteria of the second phase is young adults falling in very poor, poor and average category of VO\textsubscript{2max} from phase 1, and that is why the study was dived into two phases. The second phase will be conducted in future by other medical students under the supervision of the same supervisor.
