13
14 **Abstract**

15 **Objectives:** To investigate the seroprevalence of hepatitis E virus infection, risk
16 factors and its association with progesterone levels in pregnant women from
17 low socioeconomic background.

18 **Methods:** The cross-sectional study was conducted in Rawalpindi and
19 Islamabad, Pakistan, from January to July 2012, and comprised pregnant
20 asymptomatic healthy females from different clinics and hospitals of the twin
21 cities. Data was collected using a predesigned demographic questionnaire to
22 determine socioeconomic status. Prevalence of anti-hepatitis E virus antibodies
23 and progesterone levels were determined using enzyme-linked immunosorbent
24 assay kits.

25 **Results:** Of the 90 women, 35(39%) were in the 21-25 year age group, and
26 55(61%) belonged to low socioeconomic background. The overall prevalence of
27 seropositive hepatitis E virus immunoglobulin-G was 54(60%) and
28 immunoglobulin-M was 12(13.3%). In the first trimester, the levels of

29 progesterone were higher in patients positive for immunoglobulin-M compared
30 to immunoglobulin-G ($p < 0.001$).

31 **Conclusions:** Low socioeconomic status appeared to be a potential risk factor
32 associated with high hepatitis E virus seroprevalence and alterations in the
33 normal progesterone levels during pregnancy.

34 **Key Words:** Hepatitis E virus, HEV, Progesterone, Seroprevalence, Pakistan.

35

36 **Introduction**

37 Hepatitis E, caused by hepatitis E virus (HEV), is an infectious viral disease
38 with clinical and morphological features of acute hepatitis. Although it has been
39 reported throughout the world, it is the cause of major outbreaks of waterborne
40 hepatitis in Asia and Africa.¹⁻² In the Indian subcontinent, an epidemiological
41 study tracking hepatitis infection reported HEV as responsible for 68% of
42 sporadic hepatitis infections and fulminant hepatic failure in areas of poor
43 sanitary conditions where the virus was endemic.³ South Asia is endemic for
44 HEV and it accounts for over 50% cases of acute viral hepatitis in endemic
45 countries.⁴⁻⁵ Acute infection sometimes leads to more severe clinical fulminant
46 hepatic failure in pregnant women and is associated with very high mortality,
47 particularly during the third trimester in endemic areas, whereas it occurs
48 sporadically and is more often food-borne than water-borne in developed
49 countries.⁶

50 The prevalence of anti-HEV antibodies in healthy populations has been studied
51 in various populations worldwide to measure the extent of exposure to HEV,
52 and it was found that anti-HEV antibodies were present in persons living in all
53 geographical areas, but in disease-endemic areas, the prevalence rates among
54 healthy populations were much higher than those in non-endemic areas.⁷

55 In endemic areas, detection of immunoglobulin-M (IgM) anti-HEV suggests
56 acute infection, whereas IgG anti-HEV indicates past exposure to the virus.⁸ In
57 response to the viral infection, both IgM and IgG antibodies are detected soon

58 after, with peak antibody titers occurring 2-4 weeks after infection.⁹ The
59 persistence of IgG anti-HEV in populations is still not yet established. Large
60 hepatitis E epidemics have been reported among adults in disease-endemic
61 areas, suggesting either that anti-HEV antibody may not be fully protective or
62 that antibody levels decline with time and gradually reach unprotected levels.⁷

63 It is well established that IgM antibody to HEV appears faster during the
64 infection and disappears in about four months compared to IgG that can persist
65 for more than 10 years.¹⁰

66 In pregnancy, normal level of sex steroid hormones and immunity is altered.
67 Hepatitis E infection in pregnancy is associated with high rates of spontaneous
68 abortion, intrauterine death, and preterm labour.¹¹ The incidence of HEV
69 infection during the second and third trimesters of pregnancy is much higher
70 than in the first trimester that may cause fulminant hepatic failure in more than
71 30% patients.⁵

72 Progesterone is critical for the establishment and maintenance of pregnancy,
73 both for its endocrine and immunological effects. Progesterone receptors have
74 been proposed to play a key role in human gestation, maintenance of human
75 labour and parturition.¹² The levels of oestrogens, progesterone and beta-
76 chorionic gonadotropin (HCG) are often higher in HEV-positive patients compared to
77 HEV-negative patients or control healthy pregnant females.¹³ It has also been
78 proposed that elevated levels of sex steroid hormones in women with HEV-
79 associated acute liver failure are a risk factor predisposing women to poorer
80 outcomes.⁹

81 The current study was planned to determine the seroprevalence of HEV
82 infection in pregnant women from low socioeconomic background, and to
83 identify possible risk factors of HEV infection in relation to socio-demographic
84 factors. It was also planned to determine the levels of progesterone in HEV-
85 positive pregnant women and compare them with HEV-negative population to
86 determine the role of HEV in alteration of pregnancy-related hormone.

87

88 **Subjects and Methods**

89 The cross-sectional study was conducted in Rawalpindi and Islamabad,
90 Pakistan, from January to July 2012. After approval from the institutional ethics
91 review board of the National University of Science and technology (NUST),
92 Islamabad, the sample was raised from among pregnant asymptomatic healthy
93 females of low socioeconomic status (SES) who came for routine checkup at
94 different clinics and hospitals of the twin cities.

95 Data was collected after taking informed consent from the subjects. Those who
96 refused to participate were excluded. The participants were asked to fill out a
97 questionnaire on socio-demographic characteristics, including age, trimester,
98 gravida, family income, disease, place of previous delivery, and contact
99 number. Age was divided into four groups; 16-20, 21-25, 26-30 and 31-40
100 years. the subjects were divided into primigravida and multigravida groups,
101 and the later was further divided on the basis of place of previous delivery into
102 three categories of home, government hospital and private hospital. The sample
103 population was divided into lower and relatively higher income groups based on
104 the cut-off value of Pakistan Rupees (PKR) 10,000 per month with the lower
105 income group earning <PKR10,000. Becton, Dickinson (BD) syringes were used
106 to collect 5ml of blood samples in ethylenediaminetetraacetic acid (EDTA) tubes till serum
107 extraction. Serum was extracted from the blood samples by centrifugation at
108 10,000rpm for 5 minutes. The extracted serum was stored at -80°C.

109 For the detection of anti-HEV IgG and IgM, MicroLISA commercial kits
110 (Amgenix, San Jose, CA, USA) were used for specific detection of anti-HEV
111 IgG and IgM antibodies in human sera following the manufacturer's
112 instructions. Enzyme-linked immunosorbent assay (ELISA) readings were read
113 on Biotek Elx800 (Winooski, VT, USA).

114 The levels of progesterone was assayed using commercially available
115 quantitative RIA kit (AmgenixMicroLISA™ Progesterone Test) (San Jose, CA,
116 USA) and its assay protocol.

117 For the detection of HBV and HCV, AmgenixOnSight™ hepatitis B surface antigen
118 (HBsAg) test and AmgenixOnSight™ HCV Test (San Jose, CA, USA) were
119 performed as per the manufacturer's instructions.

120 Data, expressed as frequencies and percentages, was analysed on Microsoft
121 Excel, using one-way analysis of variance (ANOVA), unpaired T test, and one-
122 tailed Pearson correlation test. The level of significance was set at $p < 0.05$.
123 GraphPad Prism was used for developing graphs.

124

125 **Results**

126 Of the 90 women, 35(39%) were in the 21-25 year age group, and 55(61%)
127 belonged to low socioeconomic background. The overall prevalence of
128 seropositive HEV IgG was 54(60%) and IgM was 12(13.3%). The prevalence of
129 IgG and IgM were determined in three trimesters of pregnancy that varied from
130 21/36 (58.3%) in 1st trimester to 12/19 (63.1%) in the 3rd trimester for IgG, and
131 2/36 (5.5%) in the 1st trimester to 4/19 (11%) in the 3rd trimester for IgM.

132 There were 42(46.6%) primigravidae and 48(53.3%) multigravidae. Among the
133 former, 23(54.75 %) were positive for IgG compared to 31(64.5%) among the
134 latter. IgM serpositivity was observed in 5(11.9%) primigravidae and 7 (14.5%)
135 multigravidae Seroprevalence data showed variation related to place of previous
136 delivery for both IgG and IgM (Table 1).

137 In immunochromatography, of the 54 HEV-positive samples, 4(7%) were also
138 positive for HCV, but none was found positive for HBV.

139 Patients in the 1st trimester showed higher progesterone levels in IgG-positive
140 cases compared to IgG-negative population (Figure 1A). In the 2nd trimester,
141 IgG-positive patients showed lower progesterone levels compared to HEV-

142 negative patients (Figure 1B). In HEV-positive pregnant women of third
143 trimester, the levels were low compared to the healthy population (Figure 1C).

144 In HEV-IgG negative cases, the increase in hormonal levels were according to
145 the normal increase during all three trimesters (Figure 1D) compared to IgG-
146 positive patients in whom increased levels were detected in 1st trimester and
147 lower levels in 2nd and 3rd trimesters (Figure 1E).

148 Comparison of progesterone levels of HEV IgM and HEV IgG indicated that
149 the levels were significantly higher in case of acute infection compared to past
150 infection (Figure 1F).

151

152 **Discussion**

153 HEV is prevalent particularly in the developing countries where hygiene
154 conditions are poor and many affected pregnant women suffer from fulminant
155 hepatitis. In the developed countries, a small proportion of population has
156 circulatory antibodies to HEV, whereas in endemic regions, like Pakistan and
157 India, seroprevalence rates are generally higher with considerable variations
158 between regions.¹⁴ The present study reveals a seroprevalence of anti-HEV IgG
159 in healthy pregnant women with low SES to be as high as 60%. This rate is
160 much higher than that reported from previous studies done in Sargodha (16%)
161 and Karachi (20%).¹⁵ Although our findings of 13.3% IgM seropositivity
162 seemed lower than previously reported 20% from urban population of Sindh¹⁶, a
163 recent multicenter study reported a comparable IgM seroprevalence of 15.5%
164 among pregnant women from various regions of Pakistan.¹⁷

165 When compared within the region, HEV IgG seroprevalence was found higher
166 than India, where 33% pregnant women and 40-50% adult population was
167 reported seropositive.¹⁸⁻¹⁹ Reports from Bangladeshi pregnant women indicated
168 similar higher patterns with 37.6% HEV IgG seroprevalence.²⁰

169 The high prevalence of antibodies can be attributed to the sanitation conditions
170 in Pakistan. It is estimated that only 42% of Pakistani population (65% of urban

171 and just 30% of rural areas) has access to proper sanitation facilities in
172 Pakistan.²¹ In urban areas, people live in thickly-populated colonies where open
173 drains, dumping of waste in open places and mixing of drinking and wastewater
174 due to close proximity of drinking and waste water lines is common. A study
175 involving samples taken from different location of drainage outlets of Islamabad
176 and Rawalpindi showed high percentage of 40.7% of HEV circulation.
177 Alternatively, the predominant HEV genotypes in the developed countries could
178 be less virulent than those in developing countries. The HEV genotypes
179 circulating in endemic areas, including Pakistan, are mostly genotypes 1 and 2,
180 which are very uncommon in industrialised countries.²²

181 The current study showed a general increase in IgG and IgM prevalence with
182 increasing age, indicating the possibility of re-infection in IgM-positive
183 population. A gradual loss of IgG antibodies over time is an already established
184 phenomenon and antibody levels can fall to critically low levels, resulting in re-
185 infection upon re-exposure to virus.²³ Thus, seroprevalence studies could
186 potentially underestimate the exposure to HEV in a population when only IgG
187 seroprevalence is considered.

188 A gradual increase in the presence of IgG was seen across the three trimesters of
189 pregnancy. However, in case of IgM, the population of third trimester showed
190 seropositivity of 11% compared to 5.5% in the first trimester. IgG prevalence
191 ratio was higher in multigravida than that in primigravidae group. The possible
192 reason for this trend could be the age of the subjects, which was generally
193 higher in case of multiple pregnancies compared to primigravidae condition.
194 This, in turn, leads to higher chances of infection and re-infection in the
195 population. High incidence of IgG and IgM seropositivity for previous
196 deliveries at home compared to those done in private hospital were related to
197 low SES of the subjects, as reflected in the place where the previous delivery
198 had occurred.

199 Presence of HEV infection has been associated with high levels of progesterone,
200 ultimately leading to abortion and fulminant hepatic failure (FHF). The normal
201 range of progesterone is critical for the establishment and the maintenance of
202 safe pregnancy, both because of its endocrine and immunological effects. We
203 determined the progesterone levels in the sample population, and surprisingly
204 found that these levels in HEV IgG and IgM-positive population were altered
205 compared to their corresponding seronegative population. Seronegative women
206 in their first trimester were having normal range compared to their IgG-positive
207 counterparts. The results of the second and third trimesters were, however, the
208 opposite, showing decreased progesterone levels for IgG-positive subjects.

209 These findings are contrary to a study that reported increased level of
210 progesterone in later trimesters, albeit irrespective of disease status. However,
211 HCG and prolactin levels were reported high in HEV-infected women during
212 their first trimesters.²⁴ Altered progesterone levels in higher trimester could also
213 be a marker of miscarriage as indicated by a previous report.²⁵ In case of IgM
214 positive samples, the levels were found to be higher than normal in all three
215 trimesters that satisfies the previous reports about increasing progesterone level
216 with the increasing pregnancy length.²⁴ However, a big dataset may be
217 warranted for significant finding.

218 This disturbance in the progesterone levels could be due to viral factors,
219 including nutritional deficiency, super infection and folate deficiency. Further
220 investigations, like determination of levels of other pregnancy-related
221 hormones, including oestrogen and beta-HCG, reverse transcription polymerase
222 chain reaction (RT-PCR) in HEV IgG-positive patients, liver function test
223 (LFT), levels of interleukin-10 (IL-10) and IL-12 and their ratio in HEV-
224 positive patients to understand the possible mechanism, need to be done.
225 Association of malnutrition, climate, emotional or physical stress with
226 progesterone deficiency is warranted in seropositive subjects possibly through
227 case-control studies to establish the role of HEV in alteration of progesterone

228 levels. Furthermore, the role of local genotypic variations, environmental
229 conditions and immunity also needs to be determined.

230 Three HEV IgG-positive samples, which were also positive for HCV showed
231 abnormally low levels of progesterone. This might be attributed to the
232 possibility that super infection with HCV had further aggravated the disturbance
233 in the hormone levels. However, further studies are recommended in this regard.
234 The current study also compared the progesterone levels in HEV recent
235 infection and previous infection in females of first trimester. In case of recent
236 infection, the levels of progesterone were high in all samples compared to the
237 levels of previous infection of HEV. This can be compared to report from India
238 wherein alarmingly high levels of hormone were seen in FHE patients.²¹

239 However, since our study has a limitation of old data, an extended study on
240 Pakistani population may highlight important risk factors associated with HEV
241 infection, pregnancy outcome of infected pregnant females and the
242 identification of alternate transmission pathways. Moreover, the circulating
243 strains of the virus and their virulence potential need to be explored to
244 determine the need of vaccination in pregnant women.

245

246 **Conclusion**

247 Low socioeconomic status appeared to be a potential risk factor associated with
248 high hepatitis E virus seroprevalence and alterations in the normal progesterone
249 levels during pregnancy.
